

Chapter 5: IIR Filter Design

Digital Filter Design:

IIR filter and FIR filter are the two kinds of digital filters. The former one is commonly referred to as Recursive and the later as non-recursive.

Digital filters or digital signal processors are small special purpose digital computers designed to implement an algorithm that converts an input sequence $x[n]$ into a desired output sequence $y[n]$. Such filters employ as hardware, the devices such as adders, multipliers, shift registers, and delay elements. On the other hand, an analog filter employs resistors, capacitors and op-amps. As a result of this, digital processors are unaffected by factors such as component accuracy, temperature stability, long term drift, etc. that affect the analog filters.

However, digital filter designs have to consider such things as finite word size, round-off errors, aliasing, and other factors.

The difference equations that represent the IIR and FIR filters, in general, can be described as under:

$$y[n] = - \sum_{k=1}^N a_k y[n-k] + \sum_{k=0}^M b_k x[n-k]$$

Where a_k and b_k are suitable constants, $x[n]$ and $y[n]$ represent the input and output sequences. In short, the procedure of implementation of a digital filter has the following steps in order:

1. Selection of filters
2. Specification of the frequency response characteristics of the filter
3. Phase response specifications
4. Filter Design
5. Filter realization
6. Filter implementation

Filters:

The term filter is commonly used to describe a device that discriminate, according to some attribute of the objects applied at its input, what passes through it.

Filtering in electrical world is a process by which the frequency spectrum of a signal can be modified, reshaped, or manipulated to achieve some desired objectives.

Filters allow some frequencies to pass while completely blocks other frequencies.

Why filters:

- Noise reduction
- For demodulation
- To separate distinct singals
- To limit the bandwidth of signals, etc

Comparison between analog and digital filters:

	Analog Filters		Digital Filters
1.	Both inputs and outputs are continuous-time signals.	1.	Both inputs and outputs are discrete-time signals.
2.	Implementation of such filters is carried out using passive components such as resistor, capacitor, inductors and active components such as transistors, op-amps.	2.	Digital filters are implemented on a microcontroller using DSP integrated circuits. Three basic elements such as adder, multiplier and delay elements are utilized.
3.	Analog filters operate in infinite frequency range theoretically but limited in practice by the finite maximum operating frequency of the semiconductor devices used. Eg. Op-amp functions upto 100 MHz and higher frequency are handled by microwave devices.	3.	Frequency range is restricted to half of the sampling rate. It is also restricted by maximum computational speed available in particular application. In fact, is drawback of a digital filter.
4.	Main disadvantages of analog filters are its higher noise sensitivity, non-linearities, dynamic range limitations, lack of flexibility in designing and reproductivity, errors generated due to drift and variations in the value of active and passive components used in circuits.	4.	Main advantages of digital filters are that these are insensitive to noise, higher linearities, unlimited dynamic range, flexibility in software design, high accuracy, highly reliable.
5.	Analog filters have higher frequency range as well as they can interact directly with the real analog world.	5.	Digital filters require additional ADC and DAC converters section for connecting to the physical analog world.

Filters are classified as IIR and FIR as per impulse response. We will study about FIR filter in next chapter.

Comparison between IIR and FIR digital filters:

	IIR Digital Filter		FIR Digital Filter
1.	IIR digital filters are characterized by rational system function: $H(z) = \frac{\sum_{k=0}^M b_k z^{-k}}{1 + \sum_{k=1}^N a_k z^{-k}}$	1.	FIR digital filters are characterized by system function which are not rational as: $H(z) = \sum_{k=0}^M b_k z^{-k}$
2.	Impulse response of these digital filters are computed for infinite number of samples i.e. $h[n] \neq 0 \text{ for } 0 \leq n \leq \infty$	2.	Impulse response of these filters is computed for finite no. of samples i.e. $h[n] \neq 0 \text{ for } 0 \leq n \leq M-1 \text{ \& } 0 \text{ elsewhere.}$
3.	These filters do not have linear phase & these are used where some phase distortion is tolerable.	3.	These filters have linear phase characteristics. These filters are used in speech processing, it eliminates the adverse effects of frequency dispersion due to non-linearity of phase.
4.	Theoretically, these filters are stable. After truncation their coefficients, becomes unstable.	4.	These filters are realized by direct convolution, that is why these are stable.

5.	These filters have less flexibility for obtaining non –standard frequency response or for which analog filter design techniques are not available.	5.	These filters have greater flexibility to control the shape of their magnitude response and realization efficiently.
6.	These filters are usually realized by recursive method. The present output of these filters also depends on previous outputs as well as past and present inputs. It is a feedback system.	6.	These filters are generally realized non-recursively or by direct convolution. These are not feedback systems. They are not dependent on previous outputs.
7.	They are more susceptible to round-off noise associated with finite precision arithmetic, quantization error and coefficient inaccuracies.	7.	These effects are less severe in FIR digital filters.
8.	Short-time delay.	8.	Time delay increase with increase in order.
9.	These require lesser number of arithmetic operations and these have lower computational complexity and smaller memory requirements.	9.	For sharp amplitude response, we require higher order FIR digital filter. This is a main drawback of a FIR filters.
10.	IIR filters have resemblance with analog filters. The common method for IIR filter design is to design an IIR analog filter followed by analog to digital transformation methods.	10.	FIR filters are unique to discrete-time domain. These cannot be derived from analog filters.
11.	It requires less approximation parameter to design so, it is simple to design.	11.	It requires more approximation parameter so, design procedure is complex.

Filter Types: (as per frequency response)

Filters are usually classified according to their frequency-domain characteristics as **Low-pass, High-pass, Band-pass, Band-stop or Band-elimination and Notch filters.**

Figure: Magnitude responses for some ideal frequency-selective discrete-time filters.

Notch Filter

A notch filter is a filter that contains one or more deep notches or, ideally, perfect nulls in its frequency response characteristic. Figure below illustrates the frequency response characteristic of a notch filter with nulls at frequencies ω_0 and ω_1 .

Figure: Frequency response characteristics of Notch filter

To create a null in the frequency response of a filter at frequency ω_0 , we simply introduce a pair of complex conjugate zeros on the unit circle at an angle ω_0 .

$$i.e. z_{1,2} = e^{\pm j\omega_0}$$

Thus system function for an FIR notch filter is

$$\begin{aligned} H(z) &= b_0(1 - e^{j\omega_0}z^{-1})(1 - e^{-j\omega_0}z^{-1}) \\ &= b_0(1 - 2\cos\omega_0 z^{-1} + z^{-2}) \end{aligned}$$

The problem with the FIR notch filter is that the notch has relatively larger bandwidth, which means that other frequency components around the desired null are severely attenuated.

Suppose we place a pair of complex conjugate poles at ,

$$p_{1,2} = re^{\pm j\omega_0}$$

The effect of the poles is to introduce a resonance in the vicinity of the null and thus reduce the bandwidth of the notch. The system function for the resulting filter is

$$H(z) = \frac{b_0(1 - 2\cos\omega_0 z^{-1} + z^{-2})}{1 - 2r\cos\omega_0 z^{-1} + r^2 z^{-2}}$$

Notch filters are useful in many applications where specific frequency components must be eliminated. For example, instrumentation and recording systems require that the power-line frequency of 60 Hz and its harmonics be eliminated.

Advantages of using digital filters:

1. A digital filter is programmable, i.e. its operation is determined by a program stored in the processor's memory. This means the digital filter can easily be changed without affecting the circuitry (hardware). An analog filter can be changed by redesigning the filter circuit.
2. Digital filters are easily designed, tested and implemented on a general-purpose computer or workstation.
3. The characteristics of analog filter circuits (particularly those containing active components) are subject to drift and are dependent on temperature. Digital filters do not suffer from these problems, and so are extremely stable with respect both to time and temperature.

4. Unlike their analog counterparts, digital filters can be handle low frequency signals accurately. As the speed of DSP technology continues to increase, digital filters are being applied to high frequency signals in the RF (radio frequency) domain, which in the past was the exclusive preserve of analog technology.
5. Digital filters are very much more versatile in their ability to process signals in a variety of ways: this includes the ability of some types of digital filter to adapt to changes in the characteristics of the signal.
6. Fast DSP processors can handle complex combinations of filters in parallel or cascade (series), making the hardware requirements relatively simple and compact in comparison with the equivalent analog circuitry.

Characteristics of Practical Frequency-Selective Filters:

Ideal Low-pass filter have sharp cut-off from passband to stopband. There is no gap between passband and stopband in ideal lowpass filter. In practice there are some ripples tolerable in passband and stopband and some gap between passband and stopband is also observed. The practical lowpass filter is shown in figure below:

Figure: Magnitude Characteristics of Physically realizable lowpass filters.

Pass-band:

The frequency range over which a filter passes signal energy. At passband, the filters' frequency response is equal to or greater than -3dB.

Stop-band:

The frequency range over which a filter eliminates or reject signal energy. It is the band of frequency attenuated by digital filters. At stopband, the filters' frequency response is less than -3dB.

Transition band:

The frequency range between the passband and stopband.

Ripple:

It refers to fluctuations in passband or stopband of a filters' frequency versus magnitude curve. A small amount of ripple in the passband and stopband is usually tolerable.

Specifications of Analog Filters:

Gain, $G = 20\log_{10}|H(j\omega)|$ dB

Attenuation, $\alpha = -20\log_{10}|H(j\omega)|$ dB

- The width of the transition band is $\omega_s - \omega_p$
- The width of the passband is usually called the bandwidth of the filter
- The ripple in the passband is $20\log_{10}\delta_1$ decibels (dB)
- The ripple in the stopband is $20\log_{10}\delta_2$ decibels (dB)

In any filter design problem, we can specify

1. The Maximum tolerable passband ripple
2. The minimum tolerable stopband ripple
3. The passband edge frequency, ω_p
4. The stopband edge frequency, ω_s .

Based on these specifications, we can select the parameters $\{a_k\}$ and $\{b_k\}$ in the frequency response characteristics, $H(j\omega)$ which best approximates the desired specifications.

Design Procedure:

-Firstly lowpass prototype filter is designed

-Then we change LPF to any other types

LPF --- (frequency transformation) $\rightarrow$ Other types (BP, BS, HP)

Characteristics of Commonly used Analog Filters

IIR digital filters can easily be obtained by beginning with an analog filter and then using a mapping to transform the s-plane to the z-plane. Thus, the design of a digital filter is reduced to designing an appropriate analog filter and then performing the conversion from $H(s)$ to $H(z)$, in such a way so as to preserve as much as possible, the desired characteristics of the analog filter.

Analog filter is a well-developed field and many books have been written on the subject. Analog filters are good, robust and have been started since centuries.

We will be describing the importance characteristics of commonly used analog filter and introduce the relevant filter parameters. Our discussion is limited to lowpass filters.

SOME PRELIMINARIES

We discuss two preliminary issues in this section. First, we consider the magnitude squared response specifications, which are more typical of analog (and hence of IIR) filters. These specifications are given on the relative linear scale. Second, we study the properties of the magnitude-squared response.

Let $H_a(j\Omega)$ be the frequency response of an analog filter. Then the lowpass filter specifications on the magnitude-squared response are given by

$$\frac{1}{1 + \varepsilon^2} \leq |H_a(j\Omega)|^2 \leq 1, |\Omega| \leq \Omega_p$$

$$0 \leq |H_a(j\Omega)|^2 \leq \delta_2^2, |\Omega| \geq \Omega_s$$

Where ε is a passband ripple parameter, Ω_p is the passband cutoff frequency in rad/sec, δ_2 is a stopband attenuation parameter, and Ω_s is the stopband cutoff in rad/sec. These specifications are shown in figure 1, from which we observe that $|H_a(j\Omega)|^2$ must satisfy

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2} \text{ at } \Omega = \Omega_p$$

$$|H_a(j\Omega)|^2 = \delta_2^2 \text{ at } \Omega = \Omega_s$$

The manner in which specifications of a lowpass filter are given to the engineer is illustrated in figure 1(b).

The attenuation α , can be given as,

$\alpha(\Omega) = -20\log|H_a(j\Omega)|$ measured in dB which makes,

$|H_a(j\Omega)| = 10^{-\alpha(\Omega)/20}$ For the passband extending from $\Omega = 0$ to $\Omega = \Omega_p$ the attenuation should not be larger than $\alpha_{\max}$. from Ω_p to Ω_s we have a transition band. Then the specifications indicate that from Ω_s on for all higher frequencies the attenuation should not be less than $\alpha_{\min}$.

Figure (a) Magnitude squared response of analog filter.

(b) Attenuation curve

The parameters ε and δ_2 are related to parameters $\alpha_{\max}$ and $\alpha_{\min}$ respectively, of the dB scale. These relations are given by,

$$\alpha_{\max} = -20\log\left(\sqrt{\frac{1}{1 + \varepsilon^2}}\right) \Rightarrow \varepsilon = \sqrt{10^{0.1\alpha_{\max}} - 1}$$

$$\alpha_{\min} = -20\log\delta_2 \Rightarrow \delta_2 = 10^{-\frac{\alpha_{\min}}{20}}$$

$$\delta = \sqrt{10^{0.1\alpha_{\min}} - 1}, \text{ where } \delta^2 = \frac{1}{\delta_2^2} - 1$$

Butterworth lowpass filter (Maximally flat response)

This filter is characterized by the property that its magnitude response is flat in both passband and stopband. The magnitude-squared response for an N^{th} order lowpass filter is given by:

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \left(\frac{\Omega}{\Omega_c}\right)^{2N}} \quad \dots (i)$$

Where N is the order of the filter and Ω_c is the cutoff frequency in rad/sec. The plot of the magnitude-squared response is shown below:

Fig: Frequency response of Butterworth filters.

From this plot we can observe the following properties:

- At $\Omega = 0$, $|H_a(j0)|^2 = 1$ for all N .
- At $\Omega = \Omega_c$, $|H_a(j\Omega_c)|^2 = 0.5$ for all N , which implies a 3 dB attenuation at Ω_c .
- $|H_a(j\Omega)|^2$ is a monotonically decreasing function of Ω .
- $|H_a(j\Omega)|^2$ approaches an ideal lowpass filter as N tends to infinity(∞).
- $|H_a(j\Omega)|^2$ is maximally flat at $\Omega = 0$ since derivatives of all orders exist and are equal to zero.

Now,

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \left(\frac{\Omega}{\Omega_c}\right)^{2N}} = \frac{1}{1 + \varepsilon^2 \left(\frac{\Omega}{\Omega_p}\right)^{2N}}$$

Where, Ω is the normalized frequency.

The order of the filter required to meet an attenuation δ_2 at a specified frequency Ω_s is easily determined from above equation. Thus at $\Omega = \Omega_s$ we have

$$\frac{1}{1 + \varepsilon^2 \left(\frac{\Omega_s}{\Omega_p}\right)^{2N}} = \delta_2^2$$

Simplifying above equation we get

$$N = \frac{\log_{10}(\delta/\varepsilon)}{\log_{10}(\Omega_s/\Omega_p)}$$

Where,

$$\varepsilon^2 = 10^{0.1\alpha_{max}} - 1 \text{ and } \delta^2 = 10^{0.1\alpha_{min}} - 1 = \frac{1}{\delta_2^2} - 1$$

Thus the butterworth filter is completely characterized by the parameters N, δ_2 , ε and the ratio Ω_s/Ω_p . The transfer function with Butterworth response is given by

$$H_a(s) = \frac{1}{B_N(s)}$$

Where,

$$B_N(s) = 1 \text{ or } (s + 1) \times \prod (s^2 + 2\cos\psi_k s + 1)$$

Two simple rules permit us to determine ψ_k

1. a) If N is odd, then there is a pole at $\psi=0^0$;
b) If N is even, then there are poles at $\psi=\pm 90^0/N$
2. Poles are separated by $\psi=180^0/N$

Example: for N=2, poles are at $\psi=\pm 90^0/N=\pm 45^0$

$$B_2(s) = (s^2 + 2\cos 45s + 1) = s^2 + 1.414s + 1$$

The table of the transfer function for different order of the Butterworth filter is given as:

Order of Filter N	Transfer function H(s) = 1/A(s) where A(s)
1	(s+1)
2	(s ² +1.414s+1)
3	(s ² +s+1)(s+1)
4	(s ² +0.766s+1)(s ² +1.848s+1)
5	(s ² +0.618s+1)(s ² +1.618s+1)(s+1)
6	(s ² +0.518s+1)(s ² +4.414s+1)(s ² +1.932s+1)
7	(s ² +1.802s+1)(s ² +1.247s+1)(s ² +0.445s+1)(s+1)

If -3 dB frequency, or cut-off or center frequency is given we use the following formula,

$$N = \frac{\log_{10} \left(\frac{1}{\delta_2^2} - 1 \right)}{2\log_{10} \left(\frac{\Omega_s}{\Omega_c} \right)} = \frac{\log (10^{0.1\alpha_{min}} - 1)}{2\log_{10} \left(\frac{\Omega_s}{\Omega_c} \right)}$$

To find Ω_c from N, we have,

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \left(\frac{\Omega}{\Omega_c} \right)^{2N}}$$

Simplifying above equation we get,

$$\frac{\Omega_s}{\Omega_c} = (10^{0.1\alpha_{min}} - 1)^{1/2N} = \delta^{1/N}$$

$$\therefore \Omega_c = \frac{\Omega_s}{\delta^{1/N}}$$

Matching the frequency response exactly at stopband.

If we were instead to match the frequency response at passband, we would obtain

$$\Omega_c = \frac{\Omega_p}{\varepsilon^{1/N}}$$

In principle, any value of the critical frequency that satisfies

$$\frac{\Omega_p}{\varepsilon^{1/N}} \leq \Omega_c \leq \frac{\Omega_s}{\delta^{1/N}}$$

would be valid.

Chebyshev Lowpass filters (Equi-ripple Magnitude response)

There are two types of Chebyshev filters. The Chebyshev-I filters have equiripple response in the passband, while the Chebyshev-II filters have equiripple response in the stopband.

Butterworth filters have monotone response in both bands. It is noted that by choosing a filter that has an equiripple rather than a monotonic behavior, we can obtain lower-order filter.

Therefore, Chebyshev filters provide lower order than Butterworth filters for the same specifications.

The magnitude-squared response of a Chebyshev-I filter is

$$|H_a(j\Omega)|^2 = \frac{1}{1 + \varepsilon^2 T_N^2(\Omega/\Omega_c)}$$

Where N is the order of the filter, ε is the passband ripple factor, and $T_N(x)$ is the N^{th} order Chebyshev polynomial given by

$$T_N(x) = \begin{cases} \cos(N\cos^{-1}(x)), & 0 \leq x \leq 1 \\ \cosh(\cosh^{-1}(x)), & 1 < x < \infty \end{cases}$$

Where $x = \Omega/\Omega_c$.

The equiripple response of the Chebyshev filters is due to this polynomial $T_N(x)$. Its key properties are (a) for $0 < x < 1$, $T_N(x)$ oscillates between -1 and 1, and (b) for $1 < x < \infty$, $T_N(x)$ increases monotonically to ∞ .

There are two possible shapes of $|H_a(j\Omega)|^2$, one for N odd and one for N even as shown below. Note that $x = \Omega/\Omega_c$ is the normalized frequency.

From the above two response plots we observe the following properties:

- At $x = 0$ (or $\Omega = 0$): $|H_a(j0)|^2 = 1$, for N odd, $|H_a(j0)|^2 = \frac{1}{1+\epsilon^2}$ for N even.
- At $x = 1$ (or $\Omega = \Omega_c$): $|H_a(j1)|^2 = \frac{1}{1+\epsilon^2}$ for all N .
- For $0 \leq x \leq 1$ (or $0 \leq \Omega \leq \Omega_c$), $|H_a(j\Omega)|^2$ oscillates between 1 and $\frac{1}{1+\epsilon^2}$.
- For $x > 1$ (or $\Omega > \Omega_c$), $|H_a(j\Omega)|^2$ decreases monotonically to 0.

At $x=\Omega_r$, $|H_a(jx)|^2 = \delta_2^2$.

Design Equations:

Given Ω_p , Ω_s , $\alpha_{\max}$, $\alpha_{\min}$; three parameters are required to determine a chebyshev-filter:
 ϵ , Ω_c & N

$$N = \frac{\cosh^{-1}(\delta/\epsilon)}{\cosh^{-1}(\Omega_s/\Omega_p)}$$

Steps to design Chebyshev filter

1. Obtain the order of filter, N .
2. Obtain the value of ψ_k (If N is odd, then there is a pole at $\psi=0^0$ and poles are separated by $180^0/N$.)
3. Obtain the value of 'a' such that

$$a = \frac{1}{N} \sinh^{-1} \left(\frac{1}{\epsilon} \right)$$

4. Poles lie on ellipse as $s = \alpha_k \pm j\beta_k$

$$\text{where } \alpha_k = \cos \psi_k \sinh(a), \quad \text{and } \beta_k = \sin \psi_k \cosh(a)$$

$$\text{for 1st order: } (s + \alpha_k), \quad \text{for 2nd order: } [s^2 + 2\alpha_k s + (\alpha_k^2 + \beta_k^2)]$$

5. $H(s) = \frac{k}{(s+\alpha_k) \prod [s^2 + 2\alpha_k s + (\alpha_k^2 + \beta_k^2)]}$, find the value of k using $H(0) = 1$

Example # Design a Chebyshev analog filter with maximum passband attenuation of 2.5 dB at $\Omega_p = 20$ rad/sec & stopband attenuation of 30 dB at $\Omega_s = 50$ rad/sec.

Solution:

Given, $\alpha_{\max} = 2.5$ dB, $\alpha_{\min} = 30$ dB, $\Omega_p = 20$ rad/sec & $\Omega_s = 50$ rad/sec

$$\epsilon = \sqrt{10^{0.1\alpha_{\max}-1}} = \sqrt{10^{0.25}-1} = 0.882$$

$$\delta = \sqrt{10^{0.1\alpha_{\min}-1}} = \sqrt{10^3-1} = 31.6$$

For Chebyshev filter, the order is given as

$$N = \frac{\cosh^{-1}(\delta/\epsilon)}{\cosh^{-1}(\Omega_s/\Omega_p)} = \frac{\cosh^{-1}(\frac{31.6}{0.882})}{\cosh^{-1}(\frac{50}{20})} = 2.726 \cong 3$$

For $N = 3$, $\psi_1 = 0^0$, $\psi_{2,3} = \pm 180^0/3 = \pm 60^0$.

$$a = \frac{1}{N} \sinh^{-1} \left(\frac{1}{\epsilon} \right) = \frac{1}{3} \sinh^{-1} \left(\frac{1}{0.882} \right) = 0.324$$

ψ_k	$\alpha_k = \cos \psi_k \sinh(a)$	$\beta_k = \sin \psi_k \cosh(a)$	$\alpha_k^2 + \beta_k^2$	Equations
0^0	0.3297	0	0.109	$S+0.3297$
$\pm 60^0$	0.1648	0.912	0.859	$S^2+0.3296s+0.859$

$$\begin{aligned}\therefore H(s) &= \frac{K}{(s + 0.3297)(s^2 + 0.3296s + 0.895)} \\ &\quad \text{at } s = 0, H(0) = 1 \\ \Rightarrow 1 &= \frac{K}{0.3297 \times 0.895} \Rightarrow K = 0.283 \\ H(s) &= \frac{0.283}{(s + 0.3297)(s^2 + 0.3296s + 0.895)}\end{aligned}$$

Elliptic filters:

Elliptic (or Cauer) filters exhibit equiripple behavior in both the passband and the stopband. This class of filters contains both poles and zeros and is characterized by the magnitude squared frequency response

$$|H(\Omega)|^2 = \frac{1}{1 + \varepsilon^2 U_N\left(\frac{\Omega}{\Omega_p}\right)}$$

Where $U_N(x)$ is the Jacobian elliptic function of order N , ε is a parameter related to the passband ripple. The zeros lie on the $j\Omega$ -axis.

Design of IIR Filters:

$$H(z) = \frac{\sum_{k=0}^M b_k z^{-k}}{1 + \sum_{k=1}^N a_k z^{-k}}$$

IIR filters can be obtained from analog filters by using mapping function. They have infinite impulse response and contain poles, so they are unstable.

Firstly, Analog filters is designed from the desired specifications then digital filters is obtained by mapping s -domain to z -domain.

$H(s) \xrightarrow{\text{mapping}} H(z)$

Analog filter design is a mature and well-developed field, so it is not surprising that we begin the design of a digital filter in the analog domain and then convert the design into the digital domain.

An analog filter can be described by its system function,

$$H_a(s) = \frac{B(s)}{A(s)} = \frac{\sum_{k=0}^M \beta_k s^k}{\sum_{k=0}^N \alpha_k s^k}$$

Where $\{\alpha_k\}$ and $\{\beta_k\}$ are the filter coefficients, or by its impulse response, which is related to $H_a(s)$ by the Laplace transform

$$H_a(s) = \int_{-\infty}^{\infty} h(t) e^{-st} dt$$

Alternatively, the analog filter having the rational system function $H(s)$ can be described by the linear constant-coefficient differential equation

$$\sum_{k=0}^N \alpha_k \frac{d^k y(t)}{dt^k} = \sum_{k=0}^M \beta_k \frac{d^k x(t)}{dt^k}$$

Where $x(t)$ denotes the input signal and $y(t)$ denotes the output of the filter.

Each of these three equivalent characterizations of an analog filter leads to alternative methods for converting the filter into the digital domain. We recall that an analog linear time-invariant

system with system function $H(s)$ is stable if all its poles lie in the left half of the s -plane. Consequently, if the conversion technique is to be effective, it should possess the following desirable properties:

1. The $j\Omega$ axis in the s -plane should map into the unit circle in the z -plane. Thus there will be a direct relationship between the two frequency variables in the two domains.
2. The left-half plane (LHP) of the s -plane should map into the inside of the unit circle in the z -plane. Thus a stable analog filter will be converted to a stable digital filter.

IIR Filter Design:

$H(s)$ $\xrightarrow{\text{-(inverse Laplace transform)}}$ $h_a(t)$ $\xrightarrow{\text{-(sampling)}}$ $h[n]$ $\xrightarrow{\text{-(Z-transform)}}$ $H(z)$

Techniques:

1. By approximation of derivative method (**not needed in our course**)
2. By Impulse invariance method. (**imp.**)
3. By Bilinear transformation method. (**imp.**)
4. By Matched z -Transform method (**only for short notes**)

Impulse Invariance Method:

In the impulse invariance method, the objective is to design an IIR filter having a unit sample response $h[n]$ that is the sampled version of the impulse response of the analog filter. That is

$$h[n] \equiv h(nT) \quad n = 0, 1, 2, 3, \dots$$

where T is the sampling interval.

We know when a continuous time signal $x_a(t)$ with spectrum $X_a(F)$ is sampled at a rate $F_s = 1/T$ samples per second, the spectrum of the sampled signal is the periodic repetition of the scaled spectrum $F_s X_a(F)$ with period F_s . Specifically, the relation is

$$X(f) = F_s \sum_{k=-\infty}^{\infty} X_a[(f - k)F_s] \quad \text{--- (1)}$$

Where $f = F/F_s$ is the normalized frequency. Aliasing occurs if the sampling rate F_s is less than twice the highest frequency contained in $X_a(F)$.

Expressed in the context of sampling the impulse response of an analog filter with frequency response $H_a(F)$, the digital filter with unit sample response $h(n) = h_a(nT)$ has the frequency response

$$H(f) = F_s \sum_{k=-\infty}^{\infty} H_a[(f - k)F_s]$$

Or, equivalently,

$$H(\omega) = F_s \sum_{k=-\infty}^{\infty} H_a[(\omega - 2\pi k)F_s] \quad \text{--- (2)}$$

Or,

$$H(\Omega T) = \frac{1}{T} \sum_{k=-\infty}^{\infty} H_a\left(\Omega - \frac{2\pi k}{T}\right)$$

Mapping relates the z -transform of $h[n]$ to the Laplace transform of $h_a(t)$ by (generalization of above equation):

$$H(z)|_{z=e^{sT}} = \frac{1}{T} \sum_{k=-\infty}^{\infty} H_a\left(s - j\frac{2\pi k}{T}\right) \quad \text{--- (3)}$$

Where

$$H(z) = \sum_{n=0}^{\infty} h[n] z^{-n} \text{ --- (4)}$$

$$H(z)|_{z=e^{sT}} = \sum_{n=0}^{\infty} h[n] e^{-sTn} \text{ --- (5)}$$

Note that when $s = j\Omega$, eqⁿ(3) reduces to (2), where the factor of j in $H_a(\Omega)$ is suppressed in our notation.

The Mapping Relation is given by:

$$z = e^{sT}$$

If we substitute $s = \sigma + j\Omega$ and express the complex variable z in polar form as $z = r e^{j\omega}$, then

$$r e^{j\omega} = e^{(\sigma + j\Omega)T} = e^{\sigma T} e^{j\Omega T}$$

Clearly, we must have

$$r = e^{\sigma T} \quad \text{and} \quad \omega = \Omega T$$

Consequently, $\sigma < 0$ implies that $0 < r < 1$ and $\sigma > 0$ implies that $r > 1$. When $\sigma = 0$, we have $r = 1$.

Therefore, the left half in s -plane is mapped inside the unit circle in z -plane and the right half in s -plane is mapped outside the unit circle in z .

Since

$$\omega = \Omega T, \quad \frac{(2k-1)\pi}{T} \leq \Omega \leq \frac{(2k+1)\pi}{T}$$

maps into the interval $-\pi \leq \omega \leq \pi$, where k is an integer.

Thus the mapping from the analog frequency Ω to the frequency variable ω in the digital domain is many-to-one, which simply reflects the effects of aliasing due to sampling. The Impulse invariance method is inappropriate for designing highpass filters due to the spectrum aliasing that results from the sampling process.

To explore further the effect of the impulse invariance design method on the characteristics of the resulting function of the analog filter in partial-fraction form. On the assumption that the poles of the analog filter are distinct, we can write

$$H_a(s) = \sum_{k=1}^N \frac{c_k}{s - p_k}$$

Where $\{p_k\}$ are the poles of the analog filter and $\{c_k\}$ are the coefficients in the partial-fraction expansion. Consequently,

$$h_a(t) = \sum_{k=1}^N c_k e^{p_k t}, \quad t \geq 0$$

If we sample $h_a(t)$ periodically at $t = nT$, we have

$$h[n] = h_a(nT) = \sum_{k=1}^N c_k e^{p_k T n}$$

Now, with the above substitution, the system function of the resulting digital IIR filter becomes

$$H(z) = \sum_{n=0}^{\infty} h[n] z^{-n} = \sum_{n=0}^{\infty} \left(\sum_{k=1}^N c_k e^{p_k T n} \right) z^{-n} = \sum_{k=1}^N c_k \sum_{n=0}^{\infty} (e^{p_k T} z^{-1})^n$$

The inner summation in above equation converges because $p_k < 0$ and yields

$$\sum_{n=0}^{\infty} (e^{p_k T} z^{-1})^n = \frac{1}{1 - e^{p_k T} z^{-1}}$$

Therefore, the system function of the digital filter is

$$H(z) = \sum_{k=1}^N \frac{c_k}{1 - e^{p_k T} z^{-1}}$$

We observe that the digital filter has poles at $z_k = e^{p_k T}$, $k=1, 2, \dots, N$.

Comparing the analog filter $H(s)$ and $H(z)$, we can observe that the mapping relation is given by **Mapping**

Analog Domain $H(s)$	Digital Domain $H(z)$
$\frac{1}{s - p_k}$	$\frac{1}{1 - e^{p_k T} z^{-1}}$
$\frac{s + a}{(s + a)^2 + b^2}$	$\frac{1 - e^{-aT} \cos(bT) z^{-1}}{1 - 2e^{-aT} \cos(bT) z^{-1} + e^{-2aT} z^{-2}}$
$\frac{b}{(s + a)^2 + b^2}$	$\frac{e^{-aT} \sin(bT) z^{-1}}{1 - 2e^{-aT} \cos(bT) z^{-1} + e^{-2aT} z^{-2}}$

Example: Convert the analog filter with system function

$$H(s) = \frac{s + 0.1}{s^2 + 0.2s + 9.01}$$

Into a digital IIR filter by means of the impulse invariance method.

Solution: Given

$$H(s) = \frac{s + 0.1}{s^2 + 0.2s + 9.01} = \frac{s + 0.1}{(s + 0.1)^2 + 3^2}$$

We note that the analog filter has a zero at $s = -0.1$ and a pair of complex conjugate poles at

$$p_{1,2} = -0.1 \pm j3$$

Now, by method of partial fraction expansion, we obtain

$$H(s) = \frac{s + 0.1}{(s + 0.1)^2 + 3^2} = \frac{A}{s + 0.1 + j3} + \frac{A^*}{s + 0.1 - j3}$$

$$A = \left[\frac{s + 0.1}{s + 0.1 - j3} \right]_{s=-0.1-j3} = \frac{1}{2} = A^*$$

$$\therefore H(s) = \frac{\frac{1}{2}}{s + 0.1 + j3} + \frac{\frac{1}{2}}{s + 0.1 - j3}$$

Mapping from analog to Digital using impulse invariance method, we get

$$\begin{aligned} H(z) &= \frac{\frac{1}{2}}{1 - e^{-0.1T} e^{j3T} z^{-1}} + \frac{\frac{1}{2}}{1 - e^{-0.1T} e^{-j3T} z^{-1}} \\ &= \frac{1}{2} \times \frac{1 - e^{-0.1T} e^{-j3T} z^{-1} + 1 - e^{-0.1T} e^{j3T} z^{-1}}{1 - e^{-0.1T} e^{-j3T} z^{-1} - e^{-0.1T} e^{j3T} z^{-1} + e^{-0.2T} z^{-2}} \\ &= \frac{1}{2} \times \frac{2 - e^{-0.1T} 2 \cos 3T z^{-1}}{1 - e^{-0.1T} 2 \cos 3T z^{-1} + e^{-0.2T} z^{-2}} = \frac{1 - e^{-0.1T} \cos(3T) z^{-1}}{1 - 2e^{-0.1T} \cos(3T) z^{-1} + e^{-0.2T} z^{-2}} \end{aligned}$$

IIR Filter Design by the Bilinear Transformation:

Drawbacks of Impulse Invariance methods are:

- Many to one mapping
- Due to which aliasing effect occurs
- Appropriate for lowpass and limited class of bandpass filters

The bilinear transformation is a conformal mapping that transforms the $j\Omega$ -axis into the unit circle in the Z-plane only once, thus avoiding aliasing of frequency components.

Let us consider an analog filter with system function,

$$H(s) = \frac{b}{s + a} \quad \text{--- (i)}$$

This system is also characterized by the differential equation:

$$\frac{dy(t)}{dt} + ay(t) = bx(t) \quad \text{--- (ii)}$$

We integrate the derivative and approximate the integral by trapezoidal formula,

$$y(t) = \int_{t_0}^t y'(\tau) d\tau + y(t_0) \quad \text{--- (iii)}$$

Where, $y'(t)$ denotes the derivative of $y(t)$

The approximation of the integral by the trapezoidal formula at $t = nT$ and $t_0 = nT - T$ yields,

$$y(nT) = \frac{T}{2} [y'(nT) + y'(nT - T)] + y(nT - T) \quad \text{--- (iv)}$$

But from (ii)

$$y'(nT) = -ay(nT) + bx(nT) \quad \text{--- (v)}$$

Now substituting $y'(nT)$ in equation (iv)

$$y[n] = \frac{T}{2} \{-ay[n] + bx[n] + (-ay[n-1] + bx[n-1])\} + y[n-1]$$

where $x(nT) = x[n]$ and $y(nT) = y[n]$. Simplifying above equation:

$$\left(1 + \frac{aT}{2}\right) y[n] - \left(1 - \frac{aT}{2}\right) y[n-1] = \frac{bT}{2} [x[n] + x[n-1]]$$

Taking z-transform

$$\left(1 + \frac{aT}{2}\right) Y(z) - \left(1 - \frac{aT}{2}\right) z^{-1} Y(z) = \frac{bT}{2} (1 + z^{-1}) X(z)$$

Consequently, the equivalent digital filter is

$$H(z) = \frac{Y(z)}{X(z)} = \frac{\left(\frac{bT}{2}\right)(1 + z^{-1})}{1 + \frac{aT}{2} - \left(1 - \frac{aT}{2}\right)z^{-1}}$$

Or equivalently,

$$H(z) = \frac{b}{\frac{2}{T} \left(\frac{1 - z^{-1}}{1 + z^{-1}} \right) + a} \quad \text{--- (VI)}$$

Clearly, the mapping from the s-plane to the Z-plane is

$$s = \frac{2}{T} \left(\frac{1 - z^{-1}}{1 + z^{-1}} \right)$$

This is called **Bilinear Transformation**.

To investigate the characteristics of the bilinear transformation, let

$$z = re^{j\omega} \quad \text{and} \quad s = \sigma + j\Omega$$

Then bilinear mapping relation can be expressed as

$$s = \frac{2z - 1}{Tz + 1} = \frac{2re^{j\omega} - 1}{Tre^{j\omega} - 1} = \frac{2}{T} \left(\frac{r^2 - 1}{1 + r^2 + 2r \cos \omega} + j \frac{2r \sin \omega}{1 + r^2 + 2r \cos \omega} \right)$$

Consequently,

$$\sigma = \frac{2}{T} \frac{r^2 - 1}{1 + r^2 + 2r \cos \omega}$$

and $\Omega = \frac{2}{T} \frac{2r \sin \omega}{1 + r^2 + 2r \cos \omega}$

First, we note that if $r < 1$, then $\sigma < 0$,

and if $r < 1$, then $\sigma < 0$.

Consequently, the left half of s-plane maps into the inside of the unit circle in the z-plane and the right half of s-plane maps outside of the unit circle. When $r = 1$, then $\sigma = 0$ and

$$\Omega = \frac{2}{T} \frac{\sin \omega}{1 + \cos \omega} = \frac{2}{T} \tan \frac{\omega}{2}$$

or equivalently, $\omega = 2 \tan^{-1} \frac{\Omega T}{2}$

Fig. 1 Mapping between the frequency variables ω and Ω resulting from the bilinear transformation

The relationship in above equation between the frequency variables in the two domains is illustrated in Fig. 5. We observe that the entire range in Ω is mapped only once in the range $-\pi \leq \omega \leq \pi$. However, the mapping is highly nonlinear. We observe a frequency compression or frequency warping, as it is usually called, due to the nonlinearity of the arctangent function.

Frequency Warping:

For an analog filter, the frequency of the filter and the sampling frequency can help find the value of ω . $\omega = 2\pi F/F_s = \Omega T$. Here we see that there is a linear relation between Ω and ω . But the relationship we determined through the Bilinear transformation in above equation is non-linear (Fig. 5).

This change in properties when using Bilinear Transformation is referred to as Frequency warping. The non-linear relationship between Ω and ω results in a distortion of the frequency axis, as seen in Fig. 5.

Pre-warping:

We can remove the warping problem using a simple technique called pre-warping.

Fig. 2 : Frequency response with pre-warping.

In fig above, to obtain the expected response, which is straight line, we are going to merge the bilinear curve and prewarping curve so that it cancels out and gives us the straight line.

Example of Bilinear Transformation

Design a single-pole lowpass digital filter with a 3 dB bandwidth of 0.2π , using the bilinear transformation applied to the analog filter

$$H(s) = \frac{\Omega_c}{s + \Omega_c}$$

Where Ω_c is the 3 dB bandwidth of the analog filter.

Solution: The digital filter is specified to have its -3 dB gain at $\omega_c = 0.2\pi$. In the frequency domain of the analog filter $\omega_c = 0.2\pi$ corresponds to

$$\Omega_c = \frac{2}{T} \tan 0.1\pi = \frac{0.65}{T}$$

Thus the analog filter has the system function

$$H(s) = \frac{0.65/T}{s + 0.65/T}$$

This represents our filter design in the analog domain.

Now, we apply the bilinear transformation method to convert the analog filter into the desired digital filter. Thus we obtain

$$H(z) = \frac{0.65/T}{\frac{2}{T} \left(\frac{1 - z^{-1}}{1 + z^{-1}} \right) + 0.65/T} = \frac{0.245(1 + z^{-1})}{1 - 0.509z^{-1}}$$

Where the parameter T has been divided out.

The frequency response of the digital filter is $H(\omega) = \frac{0.245(1 + e^{-j\omega})}{1 - 0.509e^{-j\omega}}$

At $\omega = 0$, $H(0) = 1$ and at $\omega = 0.2\pi$, we have $|H(0.2\pi)| = 0.707$, which is the desired response.

Given $H(s) = \frac{s + 0.1}{(s + 0.1)^2 + 16}$ **and** $\omega_r = \frac{\pi}{2}$. **Find** $H(z)$.

Solution: Comparing the given $H(s)$ with the Laplace Transform equation

$$H(s) = \frac{s + a}{(s + a)^2 + \Omega_c^2}$$

We can deduce that $\Omega_c = 4$ rad/sec. The relation between Ω and ω for bilinear transformation is

$$\Omega = \frac{2}{T} \tan \frac{\omega}{2}$$

Substituting values of Ω_s and ω_r in above equation we get $T = 0.5$ sec.

Hence

$$H(z) = H(s) \Big|_{s = \frac{2}{T} \left(\frac{1-z^{-1}}{1+z^{-1}} \right)}$$

After substituting, we get

$$H(z) = \frac{0.128z^2 + 0.006z - 0.122}{z^2 + 0.0006z + 0.975}$$

The Matched-z Transformation

Another method for converting an analog filter into an equivalent digital filter is to map the poles and zeros of $H(s)$ directly into poles and zeros in the z -plane. Suppose that the system function of the analog filter is expressed in the factored form

$$H(s) = \frac{\prod (s - z_k)}{\prod (s - p_k)}$$

Where $\{z_k\}$ are the zeros and $\{p_k\}$ are the poles of the filter. Then the system function for the digital filter is

$$H(z) = \frac{\sum (1 - e^{z_k T} z^{-1})}{\sum (1 - e^{p_k T} z^{-1})}$$

Where T is the sampling interval. Thus each factor of the form $(s - a)$ in $H(s)$ is mapped into the factor $(1 - e^{aT} z^{-1})$. This mapping is called the matched-z transformation.

We observe that the poles obtained from the matched-z transformation are identical to the poles obtained with the impulse invariance method. However, the two techniques result in different zero positions.

To preserve the frequency response characteristics of the analog filter, the sampling interval in the matched-z transformation must be properly selected to yield the pole and zero locations at the equivalent position in the z -plane. Thus aliasing must be avoided by selecting T sufficiently small.

Frequency Transformation

In the Analog Domain

Suppose we have a lowpass filter with passband edge frequency Ω_p and we wish to convert it to another filter with passband edge frequency Ω'_p ,

Type of transformation	Transformation	Band edge frequencies of new filter
Lowpass	$s \rightarrow \frac{\Omega_p}{\Omega'_p} s$	Ω'_p
Highpass	$s \rightarrow \frac{\Omega_p \Omega'_p}{s}$	Ω'_p
Bandpass	$s \rightarrow \Omega_p \frac{s^2 + \Omega_l \Omega_u}{s(\Omega_u - \Omega_l)}$	Ω_l, Ω_u
Bandstop	$s \rightarrow \Omega_p \frac{s(\Omega_u - \Omega_l)}{s^2 + \Omega_l \Omega_u}$	Ω_l, Ω_u

In the Digital Domain

Type of Transformation	Transformation	Parameters
Lowpass	$z^{-1} \rightarrow \frac{z^{-1} - a}{1 - az^{-1}}$	$\omega'_p = \text{band edge frequency of new filter}$ $a = \frac{\sin[(\omega_p - \omega'_p)/2]}{\sin[(\omega_p + \omega'_p)/2]}$
Highpass	$z^{-1} \rightarrow -\frac{z^{-1} + a}{1 + az^{-1}}$	$a = -\frac{\cos[(\omega_p + \omega'_p)/2]}{\cos[(\omega_p - \omega'_p)/2]}$
Bandpass	$z^{-1} \rightarrow -\frac{z^{-2} - a_1 z^{-1} + a_2}{a_2 z^{-2} - a_1 z^{-1} + 1}$	$\omega_l = \text{lower band edge frequency}$ $\omega_u = \text{upper band edge frequency}$ $a_1 = -2aK/(K + 1),$ $a_2 = (K - 1)/(K + 1)$ $a = \frac{\cos[(\omega_u + \omega_l)/2]}{\cos[(\omega_u - \omega_l)/2]}$ $K = \cot\left(\frac{\omega_u - \omega_l}{2}\right) \tan \frac{\omega_p}{2}$
Bandstop	$z^{-1} \rightarrow -\frac{z^{-2} - a_1 z^{-1} + a_2}{a_2 z^{-2} - a_1 z^{-1} + 1}$	$\omega_l = \text{lower band edge frequency}$ $\omega_u = \text{upper band edge frequency}$ $a_1 = -2aK/(K + 1),$ $a_2 = (1 - K)/(1 + K)$ $a = \frac{\cos[(\omega_u + \omega_l)/2]}{\cos[(\omega_u - \omega_l)/2]}$ $K = \tan\left(\frac{\omega_u - \omega_l}{2}\right) \tan \frac{\omega_p}{2}$
